ABSTRACT

Sound of constant amplitude and frequency was transmitted simultaneously in three orthogonal beams over a distance of 1.5 meters in the upper ocean. Time records of the resulting phase and amplitude fluctuations of the sound beams were studied by means of auto and cross spectral analysis and correlation. The time lag between corresponding peaks of the phase fluctuation autocorrelation functions of vertical and horizontal beams indicate movement of inhomogeneities between the sound fields due to water particle motion caused by surface wave action. Envelope correlation times of the phase fluctuations are found to be approximately one-half as great in the mixed layer as in the thermocline, and are greater in the vertical than in the horizontal direction in the thermocline. Anisotropy in the thermocline is also indicated by the variance of phase fluctuation being greater for sound paths in the horizontal than in the vertical direction. The autocorrelation functions of amplitude and phase fluctuations in any one direction are similar.

ACKNOWLEDGEMENTS

I wish to express my sincere appreciation to my thesis advisor Dr. Herman Medwin for the guidance, motivation and resources which he provided for this work. Special thanks are also due Mr. William Smith, whose technical expertise in the fields of electronics, acoustics, and seamanship were invaluable in carrying out the experiment. I am also indebted to LCDR John Gossner and LCDR James Fitzgerald for their assistance in obtaining oceanographic and phase fluctuation data, to Mr. Dale Good of NUC, and the NUC Tower staff who so very ably assisted in the experiment, and to Dr. John Calhoun, who generously gave of his time in the early stages of computer program de-bugging.

This thesis serves as a technical report to Naval Ship Systems Command (Code PMS 302) which provided the major part of the financial support for the facilities, technician, and computer services required for this research. Partial support from the Office of Naval Research, Ocean Sciences and Technology Division is also acknowledged.

I. INTRODUCTION

A. BACKGROUND AND OBJECTIVES

When a sound wave is propagated in the upper layers of the ocean, both its amplitude and phase fluctuate. These fluctuations result from the motion of the medium inhomogeneities in the sound path, and motion of the medium itself. Relatively little study has been done in the relationship between the ocean microstructure and sonic fluctuations. This situation exists because early research on the interaction of sound and the ocean medium concentrated on the effect of the ocean medium on the sound wave's intensity only; it wasn't felt necessary to inquire about how the sound beam's amplitude and phase responded to the medium. However, a knowledge of how the ocean medium effects the phase and amplitude of a sound beam would now be useful from two standpoints. Devices are being developed for use in the ocean that utilize sound amplitude and phase information (acoustic imaging devices, underwater communication devices etc.) A knowledge of the effects of the ocean medium on the sound amplitude and phase is therefore mandatory. A knowledge of the relationship between the nature of the ocean's microstructure and the amplitude and phase fluctuation of a sound beam passing through that medium could enable one to derive information about the ocean microstructure by measuring such fluctuations.

The objective of this thesis was to take in-situ acoustical measurements over a range of approximately 1.5 meters in the near surface region of the ocean in order to study the relationship between sound phase and amplitude fluctuations and the nature of the medium. To do this, a constant frequency, constant amplitude sound beam was transmitted in each of three orthogonal directions simultaneously. Measurements of the position of the thermocline, swell magnitude and direction, and other environmental parameters were made. Spectral analysis and cross-spectral analysis are performed on the resulting phase and amplitude fluctuation records, and the sound phase and amplitude fluctuations are related to the behavior of the medium.

B. CAUSES OF FLUCTUATIONS

When a continuous sound beam of constant frequency and constant amplitude is transmitted through a volume of ocean, it is found that the sound beam arriving at a receiver placed some distance from the transmitter will have a fluctuating amplitude and a fluctuating phase. The causes of these fluctuations are described below.

1. Sound Amplitude Fluctuations

A sound beam traveling through an ocean medium encounters temperature and salinity inhomogeneities and "patches" of small bubbles of various sizes. The inhomogeneities and patches vary spatially with the motion of the medium (Medwin, 1970). The inhomogeneities present

a change in acoustic impedance, $\rho \cdot C$, to the sound beam, and the beam is partially reflected from the inhomogeneity, and partially transmitted through the inhomogeneity at some refraction angle. If a sound beam traveled through an ocean volume in which the inhomogeneities and bubble patches were "frozen" in place, reflection and refraction would still take place, but the received sound beam would have a constant amplitude. However, when the "frozen" inhomogeneities are allowed to move about, to move into and out of the sound beam's path, then the reflection and refraction of the sound beam changes with time, and hence the received sound amplitude will fluctuate accordingly. The motion of temperature and salinity inhomogeneities and bubble patches into and out of the sound beam's path causes sound amplitude fluctuation, due to the sound beam being both reflected and refracted by the changing acoustic impedance of the medium. The extent of the fluctuations depend upon the impedance mismatch between the medium and the inhomogeneities, size and shape of the inhomogeneities or patches, and the frequency with which they move into and out of the beam's path.

The bubbles mentioned above can have another effect on the sound beam. If the moving bubbles have a resonant frequency at or near the frequency of the sound beam, then the bubbles will resonate, absorb and scatter the incident sound beam. This reduces the sound beam's intensity, and causes the amplitude to fluctuate with time.

2. Sound Phase Fluctuation

A fluctuation in phase of the received sound beam results from a change in the integrated speed of sound propagation, C , between the source and the receiver. Such a change in C in the ocean results from the following:

a. A change in temperature, salinity, and/or the resonant bubble population in the volume of water through which the sound beam is traveling will effect the speed C . This will occur when temperature or salinity inhomogeneities and/or resonant bubbles move into or out of the path of the sound beam.

b. Motion of the medium with a vector component in the direction of sound propagation will add to or subtract from C (doppler shift). The entire ocean is in constant motion; the predominant motion encountered in the surface layers of the ocean is generally orbital motion due to surface wave action.

3. Sound Amplitude and Phase Fluctuation

The cause and effect relationship of the ocean medium and sound amplitude and phase fluctuations can be summarized as follows:

If a sound source and receiver are positioned in the upper layer of the ocean, the orbital motion of the volume of water between the source and receiver (in response to the surface wave action) carries temperature and salinity inhomogeneities and varying bubble populations into and out of the sound beam's path. Amplitude fluctuation

results due to scattering and refraction of the sound beam as it encounters the differing acoustic impedance of the inhomogeneities and bubble patches. Phase fluctuation occurs due to a change in the integrated speed of sound between the source and the receiver, and also due to the medium velocity component in the direction of sound propagation.

II. THE EXPERIMENT

A. OBJECTIVE OF THE EXPERIMENT

The objective of the experiment was to propagate constant amplitude, constant frequency acoustic signals in three orthogonal directions simultaneously at various depths in the upper layer of the ocean, and to record the resulting amplitude and phase fluctuations. Frequencies used in the experiment were 65 kHz, and 105 kHz.

B. INSTRUMENTATION

1. The Frame

a. Construction

A rigid frame was constructed in order to mount the transducers and hydrophones in a 3-dimensional configuration. Figure 1 is a photograph of a model of the frame, showing the orientation of the X, Y, and Z directions. Figure 2 is a schematic drawing of the sound fields. Figure 3 is a photograph of the actual frame in position at the experiment site. The frame was constructed of aluminum pipe with steel joints. The frame was designed to be disassembled for portability. The fully assembled frame, less instrumentation, weighed approximately 300 lb.

b. Reflective Noise Considerations

Since it was the objective of the experiment to measure the phase and amplitude fluctuation of a sound

FIGURE 3

beam traveling a direct path between the transducer and the hydrophone, it was necessary to eliminate any reflected sound. Pulse-echo testing of the frame configuration revealed points of specular reflection on the frame; acoustic absorbant rubber was affixed to the frame at these points, and all such reflections were reduced to at least 30 dB below the direct signal level.

c. Wire Tension Considerations

Scattering interference considerations necessitated mounting the hydrophones on small diameter wire. Such mounting caused vibration problems, however, which arose from Karman-vortex shedding as water flowed past the wires. Vibration of the mounting wire could cause an accelerometer effect in the hydrophone response, and more importantly, it could cause a false fluctuation in the received signal. This problem was decreased by maximizing the tension of the wires.

2. Selection of Transducers (Sources)

Since the experiment was to be performed in a frequency range from 65kHz to 105 kHz, a transducer with a well documented transmit-response in this range, and a reasonable degree of directivity was needed. One USRD type F-33 transducer and two USRD type F-41 transducers were chosen. Transmit responses for these transducers are:

<u>TRANSDUCER</u>	<u>65 kHz</u>	<u>105 kHz</u>
F-33	37dB	48dB
F-41	37dB	49dB

dB reference 1 microbar/volt at 1 meter

3. Selection of Hydrophones

A hydrophone with a flat receiving sensitivity in the frequency range of interest was the LC-10. Its measured sensitivity was:

<u>65 kHz</u>	<u>105kHz</u>
-109dB	-110dB

dB reference 1 volt/microbar

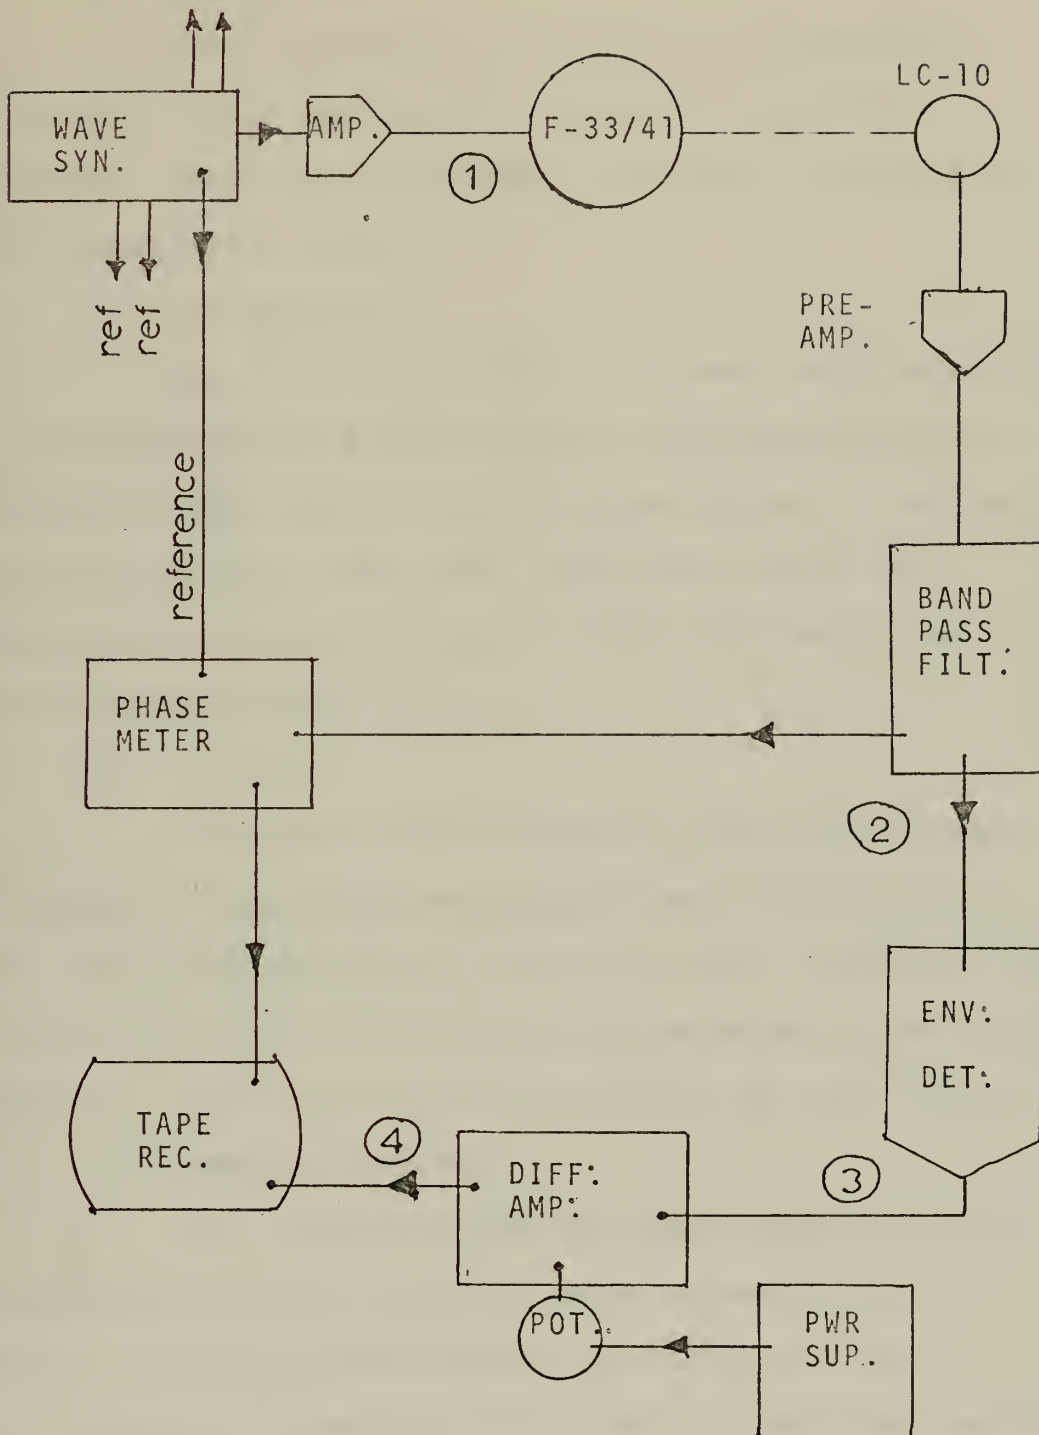

4. Circuit for Amplitude Fluctuation Detection

Figure 4 is a block diagram of the instrumentation used to measure amplitude and phase fluctuation. The phase fluctuation detection circuit is described in section II B-5. Amplitude fluctuation detection is described in the following.

a. Wave Synthesizer

A General Radio Wave Synthesizer, model 1162-A was used to generate a constant frequency, constant amplitude signal. The output of the synthesizer was divided, part of it going to a Hewlett/Packard amplifier, model 467A and then to the transducer, and part going to the phase meter as a reference signal for the phase fluctuation measurement. (section 5)

to other channels

ONE CHANNEL OF PHASE/AMPLITUDE
FLUCTUATION MEASUREMENT CIRCUIT

FIGURE 4

b. Transducers

The transducers (F-33 or F-41) transmitted an acoustic signal through the medium to the LC-10 hydrophone. One LC-10 hydrophone was used in each of the three channels, X, Y, and Z.

c. Pre-amplifier

The LC-10 generated a low level voltage which was pre-amplified by a NUS constant gain pre-amplifier. One NUS pre-amplifier was used in each channel. Two models of the NUS pre-amp. were used, model 2010 which had a gain of approximately 30 dB, and model 2030 which had a gain of approximately 20 dB.

d. Filters

The signal was filtered by means of a Krohn-Hite filter. One filter was used in each channel; two model 3322's and one model 3342 were used. The signal was band-pass filtered at ± 300 Hz on either side of the carrier frequency. The filter has a +20 and +40 dB gain option.

e. Envelope Detector

The filtered signal was then passed through an envelope detector, which is shown schematically in figure 5. The envelope detector provided full wave rectification and low-pass filtering to remove the carrier signal. The response of this envelope detector was non-linear at low input voltages levels. That is, the output of the envelope detector was not proportional to the envelope of the modulated input voltage at low input

$C = .068$ microfarrads

$R = 50$ K ohms

DIODES - Switching Type 1N277

TRANSFORMER - TA-38

SCHEMATIC DRAWING OF ENVELOPE DETECTOR
CIRCUIT

FIGURE 5

voltage levels. With the aid of a computer, a 5th order polynomial curve was fitted to the empirically determined response of the envelope detector. This curve related input AC voltage, measured in volts peak-to-peak, to output DC volts. One envelope detector was used in each direction, and a response curve was computed for each.

f. Differential Amplifier

The output of the envelope detector was a fluctuating voltage representing the fluctuations of the incoming acoustic signal. This envelope had a DC component which had to be removed prior to amplification. This DC voltage removal was accomplished with a differential amplifier, which took the difference of two input voltages and amplified it. One input to the differential amplifier was a DC voltage equal to the DC voltage to be removed from the envelope. The other input was the envelope itself. One differential amplifier was used in each channel. Two of the differential amplifiers were Princeton Applied Research Amplifiers, model TM-113, which has a variable output gain control, and a band-pass filter option. Maximum input voltage to the PAR amplifier is 0.5 volts. The other differential amplifier was a Hewlett/Packard model 2470A, which has a variable output gain control. Maximum input voltage to the Hewlett/Packard amplifier is 20 volts. The constant DC input voltage was supplied by a Hewlett/Packard model 721A power supply. A "Heli-pot" potentiometer was used to achieve accurate and

stable DC voltages. A X10 gain was applied to the output of all three channels by the variable gain of the differential amplifiers.

g. Tape Recorder

The amplified envelope was then recorded on a Precision Instrument model PI-6200 8-track magnetic tape recorder.

Figure 6 illustrates the progress of an incoming signal from the wave synthesizer to the tape recorder.

5. Circuit for Phase Fluctuation Detection

a. Phase Meter

After the signal was band-pass filtered, it was divided, and part of the signal was fed into a phase-meter. One phase-meter was used in each channel. Three different types of phase meter were used: Dranetz Phase-Meter Model 305-PA-3001, Dranetz Phase-Meter Model 305-PA-3002, and a Wiltron Phase-Meter. The phase-meter detected the phase difference between an input signal and a reference signal of the same frequency. The reference signal used was the input signal from the wave synthesizer. The output voltage of the phase-meter was proportional to the phase difference between the input and the reference signal. One degree of phase difference equals ten millivolts. The phase meter's output voltage was recorded on the 8-track tape recorder.

PROGRESS OF A SIGNAL PASSING THROUGH AMPLITUDE
FLUCTUATION DETECTION CIRCUIT.(SEE FIG. 4)

FIGURE 6

C. LOCATION OF EXPERIMENT

The experiment was carried out at the Naval Undersea Research and Development Center Oceanographic Research Tower, located approximately one mile off Mission Beach, near San Diego, California. The NUC Tower provided a rigidly fixed platform in the ocean which allowed continuous data accumulation and monitoring. Figure 7 is a photograph of the tower. It is fixed by supporting pins driven 63 feet into the ocean floor. Electrical power is supplied from the shore, thus insuring a power supply of relatively stable voltages and frequency. The tower is located in approximately 60 feet of water over a sand bottom. The instrumentation frame shown in Figure 2 was mounted on a six foot cube box standoff which was fixed to a sled. Figure 3 is a photograph of the frame mounted on the sled on the tower. The X axis was oriented in a due westerly direction. The sled was attached to a set of rails which extended from the working area of the tower to the ocean floor. The frame was raised and lowered on the rails by means of an electrically driven winch, and could be positioned at any depth.

D. INTERFERENCE FROM NEIGHBORING EXPERIMENT

A separate experiment was being carried out at the NUC tower in the proximity of this experiment. The neighboring experiment generated acoustic impulses every second from a transducer positioned near the bottom beneath the tower.

PHOTOGRAPH OF NUC OCEANOGRAPHIC TOWER

FIGURE 7

These acoustic impulses were detected by the LC-10 hydrophones of this experiment. The means of reducing this noise effect is described in section IIIb.2.

E. ENVIRONMENTAL CONDITIONS

The experiment was performed on the 8th and 9th of June, 1972. The prevailing environmental conditions are listed in Table I. Of particular note was the presence of swell waves and internal waves. The swell waves were approximately 4 ft, peak to trough, from the southwest, and with a period of approximately 15 seconds. The swell waves persisted throughout the experiment. The presence of internal waves was noted in the long term temperature fluctuations which were observed at various depths from 6 June to 9 June. These long term temperature fluctuations had a period of approximately 6 - 12 minutes. The presence of internal waves was also implied by the varying depth of the thermocline during the experiment.

Tuna and other fish were noted in the vicinity of the tower during the experiment.

F. CONDUCT OF THE EXPERIMENT

1. Choice of Record Length

A "run" consisted of radiating constant amplitude, constant frequency sound in three orthogonal directions simultaneously for approximately 20 minutes. The 20 minute run time interval was decided upon for the following reasons. Preliminary tests had shown that the sound amplitude and

PH-7	71	61/31			61
PH-8	71	61/30			61

phase fluctuations had a strong component frequency of approximately .06 HZ (corresponding to a period of about 15 seconds). Also, evidence of internal waves was observed in the preliminary fluctuation records in the form of long term amplitude and phase fluctuation; these long term fluctuations had periods of approximately 6-12 minutes. A run length long enough to record the internal wave effect would have to include several cycles, minimally 30-40 minutes. However, experiment time constraints and computer processing limitations made it necessary to limit runs to 20 minutes. This record length would allow resolution of the 15 second surface wave effect, and identification of the long period internal wave effect. However, little analytical information could be derived concerning the latter.

2. Choice of Frequencies

Two Frequencies were chosen for this experiment, 65 kHz, and 105 kHz. It has been found by Medwin (1970) that the bubble population in the upper ocean contains a large number of bubbles that are resonant at frequencies around 60 kHz. In previous experiments by Rautmann (1971), it was found that a peak dispersion of the sound speed occurs around 65 kHz; this dispersion was attributed to the presence (and resonance) of bubbles in the medium. This dispersive effect results in speeds that may be as much as 8 or 10 meters/second above or below the empirically predicted or velocimeter measured values. Near this

frequency the variance of the phase fluctuation is also very large. At 105 kHz, this dispersive effect and the large variance of the phase fluctuation is negligible.

It was decided to run the experiment at 65 kHz and 105 kHz in order to observe amplitude and phase fluctuations in a bubble affected and a non-bubble affected region.

3. Bathythermograph

A bathythermograph was taken during each run to obtain a representative gross temperature structure of the medium. The BT drop was made from the tower, approximately 40 feet from the frame.

4. Summary of Runs

Runs were performed at several depths between the surface and the bottom, at the two frequencies, 65 kHz and 105 kHz. These runs were performed during the afternoon and evening of 8 June and the morning of 9 June.

Table II is a summary of the runs.

TABLE II

III. SIGNAL PROCESSING

The data gathered during the experiment were in the form of varying analog voltage records recorded on six channels of 1/4 inch magnetic tape (X,Y, and Z direction phase fluctuations, and X, Y, and Z direction amplitude fluctuations).

A. DIGITIZATION

The data were digitized using a COMCOR 5000 - SDS - 9300 hybrid computer system of the Electrical Engineering Department, Naval Postgraduate School. It was observed from the time records that the data were generally band-limited to less than 4 HZ. A sampling rate of 50 HZ was used in the digitization process to minimize aliasing. At no time were the fluctuation records low-pass filtered. Such filtering was avoided to prevent non-linear phase shifting of the signal's component frequencies, which could result in errors in the cross-spectral analysis. A sampling pulse width of 0.1 millisecond was used, and the digitized data were blocked in records of 512 samples each. The digitization process produced a 7-track magnetic tape in octal motation, with the six channels multiplexed.

B. CONVERSION OF DATA

In order to process the digitized data on the Naval Postgraduate School's IBM 360 computer, the 7-track octal

notation tape was converted to 9-track, hexadecimal format, demultiplexed tape. In this process of conversion, scaling and "clipping" were also accomplished. The conversion program is listed on page 234.

1. Scaling of Data

During the conversion process, it was necessary to scale all of the channels. The X, Y, and Z direction phase fluctuation channels were scaled by 0.1 to compensate for the gain of the digitization process and to convert from volts to degrees of phase difference. The scaling applied to the X, Y, and Z direction amplitude fluctuations was more involved. The aim in this case was to convert the voltage records to acoustic pressures at the hydrophones for each channel. This was accomplished by computing a channel gain for each channel, based on the gain of each of the equipments. The polynomial curves described in Section IIa4.e, were employed here to describe the response of the envelope detectors. A channel was scaled as follows: for a particular channel, the DC nulling voltage (which was removed by the differential amplifier) was added to the signal; the channel gain is then applied. It was also desired to normalize all three channels of amplitude fluctuation to a common source level and a common transducer separation distance so that comparison of channels would be more meaningful. The above scaling - channel gain, source level normalization, separation distance normalization - was combined into one overall gain factor which was

applied to the X, Y, and Z amplitude fluctuation channels. This gain factor was different for each channel and for each run.

When the analysis was completed, it became evident that the scaling was in error, and unfortunately the actual values of the pressure levels at the hydrophones were unrecoverable from the data.

2. Clipping of Spikes

In many of the amplitude fluctuation records there were numerous voltage "spikes", caused by radiation from the research project mentioned in Section IID which was being conducted in the proximity of this experiment. In addition to this source of noise, there were extraneous voltage spikes which either originated in the electronics of the equipment, or resulted from a physical impulse shock to the system. Many of these spikes were removed from the time records during the digitization process. Many of those which remained in the digitized time records were removed by means of a simple "clipper" routine in the CONVERT program. When an extraneous spike was encountered in the data, the previous non-spike value was substituted for it. A threshold spike detection level had to be established for the routine; the level had to be low enough to detect the presence of a spike, but large enough so that actual data would not be interpreted as spikes. It was therefore impossible to remove all of the spikes from the time records. Samples of the time signals showing

the "raw" data and the "clipped" data are shown in Figures 8 and 9. (Note different ordinate scales)

C. ANALYSIS OF DATA

1. Analysis Scheme

Spectral and cross-spectral analysis of the fluctuation records was carried out as follows:

a. Mean Removal and De-trending

The first operations performed on each time record were removal of the mean value of the record and the removal of any linear trend of the record. The mean value (DC value) was removed so that in the succeeding analysis, the fluctuations of the signal alone would determine the nature of the results, and so that comparison of two different records would be meaningful. Removal of the linear trend of a record was accomplished by subtracting from the time record the least-mean-square fit of the record. This was done to remove any long term linear change of the signal. Such a change would have resulted not from the effects of the medium, but from instabilities in the electronics of the detecting circuits. The mean removal and the de-trending were accomplished by subroutine AVERAGE, and TREND in the analysis package.

b. Autocovariance Function

An autocovariance function was computed from a time record by a "multiply and add" process described by:

FIGURE 8

FIGURE 9

$$R_x(\uparrow) = \frac{1}{N-\uparrow} \sum_{i=1}^{N-\uparrow} x_i x_{i+\uparrow}$$

where N = total number of points in record

\uparrow = time lag

c. Power Spectral Density

Using the Wiener-Khinchine relation, the autocovariance function was Fourier transformed to produce a power spectral density

$$G_x(f) = 4 \int_0^L R_x(\uparrow) \cos(2\pi f\uparrow) d\uparrow$$

where $G_x(f)$ = Power Spectral Density

f = frequency

\uparrow = time lag

$R(\uparrow)$ = Autocovariance Function

L = Total time lag of Autocovariance

A Parzen window was applied to the autocovariance function prior to transformation for smoothing of the power spectral densities.

d. The Cross-Covariance Function

A cross-covariance function of two channels of interest (e.g. phase and amplitude fluctuations in the same direction for the same run, or phase fluctuation in two different directions for the same run) was computed. Since $R_{xy}(\uparrow) = R_{xy}(-\uparrow)$, the two parts of the cross-covariance function were computed for positive time delays:

$$R_{xy}(\tau) = \frac{1}{N-\tau} \sum_{i=1}^{N-\tau} X_i Y_{i+\tau}$$

$$R_{yx}(\tau) = \frac{1}{N-\tau} \sum_{i=1}^{N-\tau} Y_i X_{i+\tau}$$

e. The Cross-Spectral Density

The cross-spectral density was then computed by computing the cospectral density C_{xy} and the quad-spectral density Q_{xy} as follows:

$$C_{xy}(f) = 2 \int_0^L [R_{xy}(\tau) + R_{xy}(-\tau)] \cos(2\pi f\tau) d\tau$$

$$Q_{xy}(f) = 2 \int_0^L [R_{xy}(\tau) - R_{xy}(-\tau)] \sin(2\pi f\tau) d\tau$$

A Parzen window was applied to the cross-covariance function prior to transformation for smoothing of the resulting spectral densities. The cospectral density and the quad-spectral density were combined to form the cross-spectral coherence function, and the cross-spectral phase angle:

$$\text{Coherence} = \frac{C_{xy}^2(f) + Q_{xy}^2(f)}{G_x(f) G_y(f)}$$

$$\text{Phase Angle} = \tan^{-1} \frac{Q_{xy}(f)}{C_{xy}(f)}$$

f. Display of Results

The computer program used to make the above described computations is listed on pages 234 through 252. Various functions are plotted by this program:

Autocorrelation Function - The autocovariance function normalized with respect to the $\tau = 0$ value

Cross-Correlation Function - The cross-covariance function normalized with respect to the square root of the product of the $\tau = 0$ value of the component autocovariance functions

Auto-Spectrum Level - $10\log_{10}$ (power spectral density), in units of dB, reference degrees for phase fluctuation record. Relative dB are used for amplitude fluctuation records.

Coherence Function - as described in Section d. above

Cross-Spectral Phase Angle - as described in Section d. above

2. Parameters of Analysis

a. Sampling Interval

The analog voltage signals were sampled at 50 HZ when digitized. This sampling rate was chosen to insure that no aliasing of high frequencies occurred. A trial spectral analysis of a typical amplitude fluctuation record revealed that the majority of the energy of the spectrum was at frequencies less than 2 HZ. In order to reduce the amount of computer core requirements and computer time, the 50 HZ digitized data were sampled at every 8th point. This process effectively sampled the original time

signal at 6.125 HZ, with a sampling interval of 0.16 seconds.

b. Resolution

The resolution bandwidth of the power spectra is related to the autocovariance lag time and sampling interval by:

$$\Delta f = \frac{1}{(NLAG) \Delta t}$$

where NLAG = maximum number of time lags

Δt = sampling interval

c. Degrees of Freedom

The number of degrees of freedom of the power spectra is defined as

$$n = \frac{2N}{NLAG}, \quad N = \text{sample size}$$

Degrees of freedom are an indication of the normalized standard error in the variance

$$\text{error} = \sqrt{\frac{2}{N}}$$

IV. ANALYSIS OF DATA

A. RESOLUTION BANDWIDTH AND DEGREES OF FREEDOM

In computing each of the autocovariance functions, 256 time lags were taken, each lag increment being .16 seconds. Total lag time was therefore equal to $256 \times .16 = 81.96$ seconds. Therefore, the resolution bandwidth of each power spectrum was

$$f = \frac{1}{(\text{NLAG})(\Delta t)} = \frac{1}{(512)(.16)} = .0122 \text{ HZ}$$

The sample size of the time record for the majority of runs was 6656 points, $\Delta t = 0.16$ seconds. This represented approximately 17 minutes of record. The number of degrees of freedom of runs of this length was

$$n = \frac{2N}{\text{NLAG}} = \frac{2(6656)}{512} = 26$$

and the normalized standard error for the variance was

$$\frac{2}{N} = \sqrt{.077} = .278$$

Runs that were shorter than 6656 samples had correspondingly smaller degrees of freedom, and are so noted in the Summary of Runs, Table II.

B. OVERVIEW OF ANALYSIS RESULTS

Six channels of data (X, Y, and Z phase fluctuations, and X, Y, and Z amplitude fluctuations) were recorded for

5 depths at frequency 65 kHz, and 4 depths at 105 kHz. For various reasons, the data of several of the channels were of poor quality or were non-existent when played back. These bad channels were due to the presence of high background noise, and equipment/operator malfunction. The interpretations set forth in the following sections are based on fluctuation records which were relatively free of noise, and, in the experimenter's best judgment, reflected the effect of the medium on the sound beam.

One can see from Table II that a large quantity of data were gathered during this experiment. Time limitations prevented examination of many of the different aspects and implications of this data. Some of the more obvious features of the data are discussed in the following sections. This coverage is by no means extensive, but it is adequate to point out that much information about the medium can be derived from a statistical study of sound amplitude and phase fluctuations.

C. INITIAL OBSERVATIONS AND INTERPRETATION OF SPECTRAL ANALYSIS

The time records and the results of analysis of a typical pair of phase fluctuation channels are presented as figures 10 - 14. The two channels analyzed are the phase fluctuations in the Y and Z direction of run PH-4 at a depth of 18.8 feet, with a transmission frequency of 65 kHz.

FIGURE 14

1. Autocorrelation Function

a. Frequency Content

In Figure 11, observe that there are three predominant periodicities in these autocorrelation functions.

(1) Low Frequency

A very low frequency periodicity can be observed: only about one quarter of a cycle is included in the 81 second lag time. The period of this long term fluctuation which is approximately 6 minutes is substantiated by Figure 13. It is believed that this long term fluctuation is the response of the sound phase to temperature changes due to internal waves. One can also observe this internal wave effect in the time records. As the medium's mean temperature fluctuates in response to the passage of an internal wave, the sound speed, and hence the phase also fluctuates.

(2) Surface Wave Frequency

The most obvious periodicity of the autocorrelation function is the one which recurs approximately every 16 seconds. This 16 second periodicity appears in both autocorrelation functions of Figure 11, indeed, it appears in all autocorrelation functions of this experiment. As stated before, the observed periods of the surface swell waves was also about 16 seconds. It is believed that orbital motion of the medium, in direct response to the surface wave action, caused temperature and salinity inhomogeneities and bubble patches to pass into and out

of the sound field in a periodic manner. This movement causes the phase and amplitude of the sound beam to fluctuate, as explained in Section I.B.

(3) High Frequencies

There is an unsteady, low level 2 to 8 HZ fluctuation superimposed on the autocorrelation function. This may be the result of fine structure of the medium inhomogeneities or partly due to random motion of the medium, or system noise.

b. Initial Drop in Autocorrelation Function

There is a sharp drop in the autocorrelation function at the first or second time lag. This initial drop is due to the presence of intermittent noise spikes in the corresponding time records which are spaced more than 81 seconds apart (the maximum time lag of the correlation products). At the $\tau = 0$ value of the autocorrelation function all spikes in the time record are multiplied by themselves and added to the autocorrelation sum. For any other time lag, the spikes will not "line up" again, and the effect of the spikes will be distributed over the entire autocorrelation function.

2. Power Spectrum Levels

Figure 12 shows the power spectrum levels which were obtained by Fourier transforming the autocovariance function, and then applying the operation of 10Log_{10} to the transform. The 6 minute period (.003 HZ) component is less than our resolution (.01 HZ). Its effect appears

but is unresolvable in the frequency range 0 - 0.015 HZ. The strong frequency component due to surface swell is observed at approximately .065 HZ in the spectra for both the Y and Z directions. Components at higher frequencies are at least 10 dB down from the spectrum level of the $f = .065$ HZ component, and probably represent the effect of other sea surface components, and noise of the system.

3. Cross Correlation Function

The cross-correlation function shows a strong cross-correlation between the two signals at about 16 second intervals. The envelope of the 16 second periodicities suggests that a 6 minute cross-correlation periodicity also exists. However, this cannot be verified due to the relatively short lag time.

4. Coherence

If the Y direction phase fluctuation and the Z direction fluctuations were completely unrelated, the coherence function would be equal to zero. If the coherence function equals 1, the two channels are completely correlated and are linearly related. In general, if the coherence function is greater than zero but less than unity, one or more of the following three situations exists:

a. Extraneous noise is present in the measurements of either or both channels.

b. The relationship between the Z phase fluctuation and the Y phase fluctuation is not linear.

c. There are inhomogeneities or bubble patches affecting one channel which do not effect the other channel; that is, the propogation is not isotropic.

The coherence function shown in Figure 14 ranges from 0 to 0.75; no coherence function computed in this experiment exceeded 0.8. Of the three situations listed above, situation C is the one most likely to have caused the coherence to be less than unity.

As might be expected from observing the similarities of the autocorrelation functions, the coherence function has a relative maximum value at frequencies of approximately .005, .065, .085, .125, and .170 HZ, the strongest maximum being at .065 HZ. These frequencies correspond to frequencies which are common to the two channels, the .065 HZ frequency being the strongest common frequency.

5. Cross-Spectral Phase Angle

The cross-spectral phase angle function has significance only at frequencies for which the coherence is greater than zero. For example, at .065 HZ, where the coherence equals .75, the phase angle equals -30° . This measurement can be explained in the following way: Observe the alignment of the 16 second peaks of the two autocorrelation functions, Figure 11. Careful measurement of the time lag value associated with corresponding peaks shows that the Z peak always precedes the Y peak by 1 to 1.5 seconds. In other words, the correlation peaks of the

Z phase fluctuation channel leads the correlation peaks of the Y fluctuation channel by 1 to 1.5 seconds. Essentially the same changes of medium took place in the Y and Z directions but they are happening 1 to 1.5 seconds sooner in the Z direction. The frequency of this fluctuation is about .065 HZ; at this frequency, 1.5 seconds corresponds to approximately 30° . Therefore the cross-spectral phase angle is a measure of the phase difference between the two channels in question, at a particular fluctuation frequency.

The fact that there is a phase difference in the occurrence of the phase fluctuation of the sound beam in the Y and Z directions as shown by the cross-spectral phase angle, or by direct measurement of the time lag between peaks of the autocorrelation functions, indicates that moving inhomogeneities are causing the 16 second period fluctuations. It is suggested that it takes a particular patch of water on the order of 1 or 1.5 seconds to move from the axis of the Y direction sound field into the axis of the Z direction sound field, a distance of approximately one meter; this implies a speed of approximately 65 to 100 centimeters per second. Fringe field interaction would occur at about one-half meter at half this speed. From the swell wave point of view, if the motion were solely orbital at frequency 0.065 HZ and amplitude of about 50 cm. (this was the amplitude of the observed

swell), the orbital velocity would be approximately 25 cm/second. The moving patch explanation appears to be quite reasonable.

It was found that a phase difference in the occurrence of the 16 second sound phase fluctuation between the Y and Z directions was common. Table III shows the cross-spectral phase angle of the fluctuations for several runs. There is consistency in the magnitude of the angle but not in the sign. This can be explained by the randomness of whether, for example, a hot patch starts from the Y axis field or the Z axis field position at the beginning of the run; this position is of course random, so that the sign of the phase would be random.

D. CORRELATION TIME AS A FUNCTION OF THE SOUND FIELD'S RELATION TO THE THERMOCLINE

For the purpose of this work, correlation time is defined as that time required for the envelope of the autocorrelation function to decay to $1/e$ of its initial value. In cases where there is an initial drop D at the first lag value, $t = .16$ seconds, the correlation time is taken to be that time required for the envelope of the autocorrelation function to decay to $(1-D)/e$. (See Section IV.C.1.b. for the explanation of the cause of steep initial drops in the autocorrelation function.)

It is assumed that the speed of sound in the upper ocean is primarily a function of temperature and bubbles

TABLE III

(Rautmann 1971). The periodic recurrence of a particular integrated speed of sound along a sound axis implies a stable (not changing with time) temperature microstructure. The correlation time of sound phase fluctuations is an indication of the periodic recurrence of the integrated speed of sound of the medium along the sound axis. A long correlation time indicates stability in the temperature structure of the medium in the vicinity of the sound field. In other words, a volume of water having a slowly changing (stable) temperature microstructure was moving through the sound field with periodic motion in response to surface wave action (orbital motion). Short correlation time indicates instability in the temperature microstructure; that is, the volume of water moving through the sound field periodically in response to surface wave action has a more rapidly changing temperature microstructure, resulting in a less periodic recurrence of an integrated speed of sound along the sound axis.

The behavior of the correlation times of phase fluctuations in the Y and Z directions have been examined. It is shown that the correlation times of the phase fluctuations in the Y and Z directions were greater (greater stability of the medium) when the sound field was in the thermocline, than when it was in the well mixed layer.

Figures 15 to 18 are diagrams of the temperature structure of the ocean in the vicinity of the tower during

FIGURE 18

runs PH-2 (31 ft, 65 kHz), PH-3 (25 ft, 65 kHz), PH-4 (18.8 ft, 65 kHz), and PH-5 (7 ft, 65 kHz). The position of the Y and Z axes for each run is also indicated on the figures. This temperature structure varied during each run, as the thermocline moved up and down with the medium with a periodicity of 6 to 10 minutes. The temperature structure shown is probably fairly representative of the temperature that prevailed during the entire run, but is truly representative of the actual temperature structure only at the precise time at which it was taken. Since the run durations were 1 1/2 to 3 times the internal wave periodicity, data processing gives average results over the changing medium. Figures 19, 20, 21, and 22, are the 17 minute time records of the channels of interest of runs PH-2, 3, 4, and 5. A star on each time record marks the time the BT was taken. During run PH-5 (7 ft, 65 kHz), the Z axis was located well within the well mixed isothermal layer. During run PH-4 (18.8 ft, 65 kHz) and Y and Z axes were located in the vicinity of the boundary between the surface layer and the first thermocline. During run PH-3 (25 ft, 65 kHz), and PH-2 (31 ft, 65 kHz) the Y and Z axes were located in a thermocline.

The autocorrelation function of these runs are shown in Figures 23, 24, 25, and 26. The corrected correlation times are plotted as a function of depth, and as a function

FIGURE 26

of the distance from the Y axis sound field to the lower boundary of the surface mixed layer. (See Figure 27) It can be seen that the correlation times of runs PH-2 (31 ft, 65 kHz) and PH-3 (25 ft, 65 kHz) where the Y and Z axes were located well within the thermocline, is greater than the correlation time of run PH-5 (7 ft, 65 kHz), where the Y and Z axes were within the surface layer, and run PH-4 (18.8 ft, 65 kHz), where the Y and Z axes were located in the transition region between the surface layer and the thermocline. It is believed that this behavior of the correlation time is due to the following.

Measuring the decay time of the autocorrelation function envelope to $(1-D)/e$, vice the decay time of the 16 second periodicities, measures the de-correlation of the long-term (6 to 10 minute periodicities) phase fluctuation. The long term fluctuations are believed to result from long term temperature fluctuations of the medium of the sound field, which reflect the medium movement in response to the passage of an internal wave.

In the surface mixed layer, the temperature, salinity and bubble microstructure is random; Skudrzyk (1963) describes this random distribution as "temperature patches" of varying sizes. On the other hand, since the work of Woods (1968), a picture of the more stable thermocline has evolved. The thermocline is said to consist of alternate sheets of high temperature gradients (order of cm. thick) and plates of low temperature gradient water

FIGURE 27

(order of a meter thick), both parallel to the sea surface. If a volume of this well structured thermocline water is moved vertically into and out of a sound field with an approximate periodicity, as in response to the passage of an internal wave, the sound speed fluctuation, and therefore the phase fluctuations should reflect the periodic recurrence of particular temperatures. In contrast to this, consider the surface layer where the temperature structure is random. There will be only random recurrence of particular temperature structures for the same long term medium movements since the motion of the well mixed layer has a superimposed random horizontal and vertical motion of the inhomogeneities. Hence, the long term (envelope) fluctuations of the autocorrelation function will decorrelate faster (will have a shorter correlation time) in the surface layer than in the thermocline. This behavior is in fact observed in the shorter correlation time of runs PH-5 which was located in the surface layer, and PH-4 which was located in the transition region between the surface layer and the first thermocline, and the longer correlation times of runs PH-3 and PH-2, both of which are located in a thermocline.

E. Z DIRECTION CORRELATION TIME VERSUS Y DIRECTION CORRELATION TIME

In runs PH-2 (31 ft, 65 kHz) and PH-3 (25 ft, 65 kHz) which took place in the thermocline, the Z direction phase

fluctuations have a longer correlation time than the Y direction phase fluctuation; while in run PH-4 (18.8 ft, 65 kHz) which took place in the mixed layer, the Y and Z direction phase fluctuations have approximately equal correlation times. This may well be due to the presence of stable layered patches of isothermal water in the thermocline, and isotropically random patches of isothermal water in the mixed layer. As stated in Section IV.D, by defining the correlation time to be the time associated with the envelope decay, a correlation time is a measure of the stability of the medium over long term changes; in this case changes resulting from internal waves. Long term periodicities of a phase fluctuation depend on a particular value of integrated sound speed recurring in the sound field at regular (long term) intervals. As previously mentioned, there is evidence that there are regions of thermocline "sheets" and "plates" parallel to the surface of isothermal water in the thermocline.

If the medium undergoes vertical movement, the extent of the periodicity of long term phase fluctuations in the Y direction will depend on a recurring isothermal plate at the Y axis, since the Y axis sound beam travels horizontally through the isothermal plate. In contrast, the Z axis sound beam travels vertically through horizontal plates of isothermal water. The integrated sound speed over the path is the average temperature of the horizontal plates. Long term periodicities of the phase fluctuation

in the Z direction depend on the recurrence of an average sound speed over one or more isothermal plates; such a periodicity in the Y direction depends on the recurrence of a particular isothermal plate.

Therefore, in a thermocline, where a fairly stable gradient prevails, long term phase fluctuations are more stable in the Z direction than in the Y direction because the orbital movement of the medium is less likely to cause deviations from a recurring average sound speed in the Z direction than in the Y direction.

Note that for run PH-4 (18 ft, 65 kHz) which was in the transition region between the thermocline and the mixed layer, the Y and Z correlation times are nearly equal. The mixed layer is composed of randomly distributed patches. It is therefore equally likely to have an integrated sound speed repeated in the Y direction as in the Z direction.

Thus, for the cases examined, sound phase correlation times are not isotropic in the thermocline, but are nearly isotropic in the mixed layer.

F. Y DIRECTION VARIANCE VERSUS Z DIRECTION VARIANCE

Figure 28 is a graph of the variance of Y and Z direction phase fluctuations for runs PH-2 (31 ft, 65 kHz), PH-3 (25 ft, 65 kHz), and PH-4 (18.8 ft, 65 kHz). The variance of a time record is defined as the zero lag value of the autocovariance function. Because of the sharp initial drop in many of the autocovariance functions due

FIGURE 28

to noise spikes, the value of the autocovariance function at $\tau = 0.16$ or 0.32 seconds is a more accurate estimate of the variance than the $\tau = 0$ value. Therefore, in comparing the variances of the Y and Z direction fluctuations of runs PH-2,3, and 4, this corrected variance was used.

Chernov (1960) has shown that the variance of a phase or amplitude fluctuation in a random medium is proportional to the length of the transmission path. The Y and Z direction paths were of different lengths, and although Chernov's assumptions are not fulfilled in the thermocline, all variances were normalized to one meter by dividing each variance by its path length. The corrected and normalized variance versus run depth is plotted in Figure 28. The Y direction variance is always greater than the Z direction variance. This may also be due to the layered structure of the medium. If horizontal plates of various thicknesses are moving through the sound field due to orbital motion, the integrated phase fluctuations will be more sensitive to a vertical movement in the Y direction than in the Z direction, because the Y direction sound beam passes horizontally through a horizontal isothermal "plate". A small movement could shift a new "plate" and therefore a sharp temperature change into the Y axis, while the integrated speed and temperature over the Z direction would not be so greatly effected.

The Z direction variance of the phase fluctuations for run PH-5, which took place in the surface mixed layer, is much greater than the variances of runs PH-2, PH-3, and PH-4. This is an expected result due to two characteristics of the surface mixed layer: the random orientation of temperature patches and the presence of bubble populations which have been found to be resonant at 65 kHz. (Rautmann, 1971, Fitzgerald, 1972)

It is concluded that the variance of the phase fluctuation in the thermocline is not isotropic.

G. CORRELATION OF PHASE AND AMPLITUDE FLUCTUATIONS

Chernov (1950) has derived expressions for the temporal autocorrelation function of the phase and amplitude fluctuations of a sound beam in an isotropic, stationary random medium. He concludes that the temporal autocorrelation function of the phase fluctuations equals the temporal autocorrelation function of the amplitude fluctuations. The autocorrelation function of phase and amplitude fluctuations of this experiment can be compared to see how closely they approach the Chernov equality.

In examining the autocorrelation functions, it will be noted that in many cases the autocorrelation function has a very steep initial drop at $t = .6$ seconds after which it decays more normally. It is believed that this sharp initial drop is due to extraneous, widely spaced noise spikes, as explained in Section IV C.1.b. Therefore,

in comparing phase and amplitude fluctuations, the effects of the extraneous spikes should be removed from each function prior to comparison. This could be done by taking the 0.16 second or 0.32 second value of the autocovariance function as the normalizing factor in each case. This re-calculation of the autocovariance function was not done, for lack of time, but a roughly equivalent correction was made, that of merely subtracting the initial drop from each of the autocorrelation functions. Figure 29 shows the autocorrelation function of the Z direction phase and amplitude fluctuations from PH-8 for 65 kHz, 26.8 ft. depth. Figure 30 shows the same two autocorrelation functions with the initial drop subtracted from each function. It can be seen that the phase and amplitude fluctuation autocorrelation functions are very similar in this case. This is an example of excellent agreement between the phase and amplitude fluctuation autocorrelation functions. Figure 31 shows the X direction phase and amplitude autocorrelation functions from PH-7 for the 65kHz, 44.2 ft. depth run. In this case, the phase fluctuation is greatly affected by extraneous noise spikes, and by high frequency periodicities. The extraneous noise spikes cause the initial sharp drop at $\tau = .16$ or $.32$ seconds. The high frequency periodicity is either high frequency noise, or the effects of aliasing of high frequency noise. In either case, these high frequency signals are not caused by the effects of the ocean medium on the sound wave, as explained in

FIGURE 32

Section IV.C.1.b; hence, these high frequency effects are not considered in this analysis. In Figure 32, the extraneous noise spike effect has been removed, and the phase autocorrelation function has been smoothed. It can be seen that the phase and amplitude autocorrelation functions are still similar in appearance, and have relative maxima and minima at about the same lag times.

Other pairs of phase and amplitude autocorrelation functions are shown in Figures 33 - 38. If the initial sharp drop is ignored, it will be observed that their behaviors are essentially the same. Thus, for the case observed here, it appears that the Chernov statement holds, to varying degrees. The reasons why the Chernov equality fails are: 1) the presence of different amounts of extraneous noise spikes in each signal causing a sharp initial drop, and 2) the presence of extraneous high frequency signals in one of both channels (noise), and most importantly, 3) the phase fluctuations are sensitive to long term temperature changes while the amplitude fluctuations are not. Chernov assumed that random inhomogeneities in the sound field were the sole cause of fluctuations; he did not consider long term anisotropic temperature changes, such as those that result from the passage of an internal wave.

FIGURE 38

V. CONCLUSIONS

The following conclusions are drawn based on the preceeding analysis:

A. Phase and amplitude fluctuations of a 65 kHz and 105 kHz sound beam in the surface layer of the ocean are caused by the motion of medium inhomogeneities of varying acoustic impedance in the sound field. Inhomogeneity motion arises from two main sources:

1. Orbital motion of the medium in response to surface wave action, and
2. Motion of the medium in response to the passage of internal waves.

The dominant frequency components of the phase and amplitude fluctuations are those of the surface waves and internal waves.

B. The envelopes of the autocovariance functions of the phase fluctuations in a horizontal and a vertical sound beam of 65 kHz decorrelate (reduce to $1/e$ of their initial value) faster in the surface mixed layer than in the thermocline. It is believed that this is an indication of two characteristics of the mixed layer: the greater instability of the temperature structure in the mixed layer, versus that in the thermocline, and the presence of bubbles resonant at 65 kHz in the mixed layer.

C. In the thermocline, the autocovariance function of the phase fluctuations of a horizontal sound beam decorrelates faster than the autocovariance function of the phase fluctuations of a vertical sound beam. It is believed that this results from a layered "plate" temperature structure of the thermocline. Therefore, the correlation time in a thermocline is not isotropic.

D. In the thermocline, the variance of the phase fluctuation of a 65 kHz sound beam in the horizontal direction is greater than the variance of the phase fluctuations in the vertical direction. It is believed that this is a result of a layered "plate" temperature structure of the thermocline. Therefore, the variance in the thermocline is not isotropic.

E. From C. and D. above, it is concluded that the medium in the thermocline is anisotropic.

F. The autocorrelation function of the phase fluctuation approximately equals the autocorrelation function of the amplitude fluctuations for a 65 kHz sound beam traveling through 1 meter of the surface layer of the ocean. This result reinforces and extends the theoretical work of Chernov (1950) which predicted that the autocorrelation functions of the phase and amplitude fluctuations of a sound beam traveling through a random, stationary isotropic medium would be equal.

VI. RECOMMENDATIONS FOR FUTURE EXPERIMENTS

A. EXPERIMENTAL TECHNIQUE

The results of this experiment demonstrate the feasibility of obtaining useful information about the microstructure of a volume of ocean water by studying the sound phase and amplitude fluctuations of sound passing through the volume. It also points out some of the pitfalls in making such measurements. For those who repeat this experiment, or perform similar experiments in the future, the following recommendations are offered.

1. Use differential amplifiers that are not limited to a low input voltage. This will allow operation well above many of the noise levels of the system. The PAR 113 differential amplifier, although ideal from the point of view of internal electrical noise, was poorly suited for this purpose.

2. To obtain any variance information from the amplitude fluctuation records, the system gains must be known exactly (phase fluctuation measurements will not be effected by varying gains or voltage levels). Careful measurement of these gains, preferably before the experiment, is the only way to obtain such information. System gain measurements should be done with the detection circuit fully assembled, vice piecemeal.

B. AREAS FOR FUTURE INVESTIGATION

1. Much more information can be gleaned from the data of this experiment. Analysis results of runs not previously considered are included as Appendix A. It is felt that further analysis of these data would be fruitful.

2. Concurrent measurement of sound amplitude and phase fluctuation, particle velocity, and temperature in the sound field would shed more light on the relationship between medium motion and sound phase and amplitude fluctuation. By making such concurrent measurements of particle velocity, temperature, and sound phase and amplitude fluctuation, it should be possible to deduce the role of resonant bubbles in the acoustic fluctuations.

APPENDIX A

Analysis Results For Various Runs

Table II lists the experimental runs which were analyzed by the computer programs CONVERT and ANALYSIS. Various outputs of this analysis are displayed throughout the body of the thesis.

Appendix A contains the remainder of the analysis. This information is included to permit comparison with future studies in this field, and for further analysis of this data at some future time. A typical "set" of results for a given run are (1) Temporal Autocorrelation Function, (2) Power Spectrum Level, (3) Temporal Cross-Correlation Function, and (4) Coherence Function and Cross-Spectral Phase Angle. Some sets are not complete, as portions of them were displayed in the body of the thesis.

Interpretation of these outputs is explained in Section IV-C. The ordinates of the cross-correlation function graphs are labeled incorrectly; they should be labeled as in Figure 13.

ANALYSIS PACKAGE

THIS PROGRAM IS AN ANALYSIS PACKAGE FOR PERFORMING SPECTRAL ANALYSIS OF TIME RECORDS. TWO TIME RECORDS TO BE CONSIDERED ARE FIRST READ INTO COMPUTER STORAGE FROM MAGNETIC TAPE. THE AUTOCOVARIANCE FUNCTION IS THEN COMPUTED FOR EACH TIME RECORD. THE AUTOCOVARIANCES ARE THEN FOURIER TRANSFORMED TO OBTAIN THE POWER SPECTRUM OF EACH OF THE TIME RECORDS. THE TWO TIME RECORDS ARE THEN CROSS-CORRELATED, AND THE CROSS-CORRELATION FUNCTION IS TRANSFORMED TO YIELD THE CO-SPECTRUM AND THE QUAD-SPECTRUM.

THE CO-SPECTRUM

AND THE QUAD-SPECTRUM ARE COMBINED TO YIELD THE COHERENCE FUNCTION AND THE CROSS-SPECTRAL PHASE ANGLE OF THE TWO TIME RECORDS.

NTS= NUMBER OF TIME SAMPLES

MLAG = NUMBER OF TIME LAGS

DT = TIME INCREMENT

DHZ = FREQUENCY SPACING

DHZ = $1/(2*TM)$

TM = DT*MLAG

FBHZ = LOWEST FREQUENCY (HZ)

FBHZ = $1/(2*TM)$

FEHZ = HIGHEST FREQUENCY OF INTEREST (HZ)

FEHZ = $1/(2*DT)$

CALX1 = CALIBRATION FACTOR FOR TIME SERIES F1

CALX2 = CALIBRATION FACTOR FOR TIME SERIES F2

H = WATER DEPTH (METERS)

X2 = DEPTH OF WAVE PRESSURE TRANSDUCER BELOW SURFACE

DIMENSION F1(7000), F2(7000), GAR(512), AX(2048), A(256), BX(2048)

ABSTRACT

Sound of constant amplitude and frequency was transmitted simultaneously in three orthogonal beams over a distance of 1.5 meters in the upper ocean. Time records of the resulting phase and amplitude fluctuations of the sound beams were studied by means of auto and cross spectral analysis and correlation. The time lag between corresponding peaks of the phase fluctuation autocorrelation functions of vertical and horizontal beams indicate movement of inhomogeneities between the sound fields due to water particle motion caused by surface wave action. Envelope correlation times of the phase fluctuations are found to be approximately one-half as great in the mixed layer as in the thermocline, and are greater in the vertical than in the horizontal direction in the thermocline. Anisotropy in the thermocline is also indicated by the variance of phase fluctuation being greater for sound paths in the horizontal than in the vertical direction. The autocorrelation functions of amplitude and phase fluctuations in any one direction are similar.
